

MAGNETIC RECONNECTION IN SPACE AND LABORATORY PLASMAS AND ITS IMPLICATION IN TOKAMAK PLASMA CONFINEMENT

Chase Johnson

December 10, 2014

Abstract

Magnetic reconnection is the topological restructuring of magnetic field lines in high temperature plasmas. The aim of this paper will be to describe the fundamental physics of magnetic reconnection and discuss the various MHD models to describe magnetic reconnection. Magnetic reconnection as observed in both space plasmas and laboratory plasmas results in significant changes in kinetic and thermal properties of the plasma. This inherently deteriorates the ability to confine plasma in the laboratory. The second part of this paper will describe the fundamentals of sawtooth instabilities triggering magnetic reconnection in tokamak plasma devices. Due to the undesirable effects of magnetic reconnection in laboratory plasmas, several techniques have been developed to control sawtooth instabilities. The efficacy of these techniques to include current drive schemes and ion population control will be discussed.

1 Reconnection Defined

Reconnection is the rearranging of the magnetic topology where magnetic field lines are broken and then recombine and is shown in Figure 1.^{16,19,20} This is an important process to understand in astrophysics, laboratory plasma science, and others due to its disruptive effects. The process of reconnection changes the macroscopic quantities of plasmas through:¹⁶

- conversion of magnetic energy into heat
- accelerate plasma by converting magnetic energy into kinetic energy
- create shockwaves, current filamentation, and turbulence
- affect fluxes of fast particles and heat due to changes in global magnetic field lines

The first two effects are especially important for stability of confined plasmas due to causing major and minor disruptions in tokamak discharges that will be discussed in this paper.²⁰

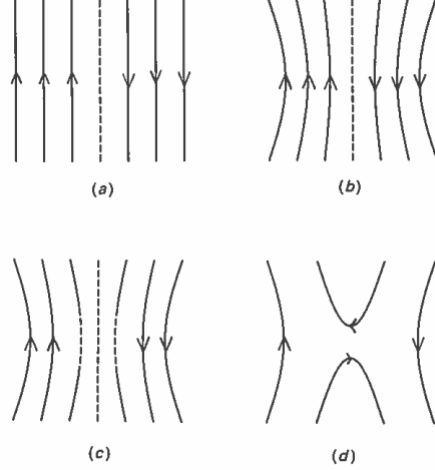

Figure 1: An initial perturbation generates magnetic pressure to counter. However, magnetic field diffusion occurs rapidly in locations of strong flux gradient. As magnetic field diffuses, perturbation is allowed to grow and alter topology.¹¹

1.1 Reconnection in Space Plasmas

Magnetic reconnection is seen directly in many aspects of space plasmas. Solar flares and coronal mass ejections were one of the first events studied to understand magnetic reconnection.²⁰ Coronal mass ejections and solar flares result from converting magnetic energy into heat and particle energy during a magnetic reconnection event.¹⁶ Additionally, a small scale reconnection model is thought to be responsible for the higher density slow solar wind originating from the Sun's equatorial region.¹⁶ Reconnection between solar wind magnetic field lines and the Earth's magnetosphere field lines is also thought to be responsible for the penetration of solar particles to penetrate the magnetosphere (Figure 2).^{7,16}

Understanding reconnection in space plasma is vitally important to protecting space satellites, astronauts, and even terrestrial utilities from the damaging effects of highly energized charged particles from solar plasma.

1.2 Reconnection in Laboratory Plasmas

Reconnection is believed to be responsible for various anomalies in tokamak, reverse pinch, and spheromak devices. In tokamak devices, magnetic reconnection

Figure 2: Reconnection at magnetopause⁷

tion manifests in a periodic reorganization of core plasma density and temperature(Figure 3).

Figure 3: Soft X-ray emissions give core temperature indications. This shows the core plasma temperature periodically dropping associated with an increase in edge plasma temperature.²

In reverse pinch and spheromak device, magnetic reconnection plays a role in the magnetic relaxation. Magnetic relaxation is a self-organization of confined plasma that is thought to be a preferred state of minimal helicity.^{8,20} Magnetic reconnection events are believed to be a driving factor in changes of helicity and therefore a driving factor for confined plasma self-organization.⁸ Understanding these phenomena is important and is a driving factor in the development of new confinement techniques in the field of plasma fusion.^{1,2,18}

1.3 Fundamental Physics of Reconnection

Davidson, Priest, and Garcia all present very good introductions to the relevant magnetohydrodynamics of magnetic reconnection, in particular Chapter 6 of Eric Priests textbook. For this paper we will focus on the derivation of magnetic diffusion and how this plays a role in magnetic reconnection. Beginning with the differential forms of Ampere's Circuit Law and Gauss' Mag-

netic Law:

$$\nabla \times \vec{H} = \vec{J} + \frac{\partial \vec{D}}{\partial t} \quad \text{or} \quad \nabla \times \vec{B} = \mu \vec{J} + \frac{1}{c^2} \frac{\partial \vec{E}}{\partial t}$$

$$\nabla \cdot \vec{B} = 0$$

And combining them with Ohm's Law:

$$\vec{J} = \sigma \left(\vec{E} + \vec{v} \times \vec{B} \right)$$

We arrive at the result,

$$\frac{\partial \vec{B}}{\partial t} = -\nabla \times \left(-\vec{v} \times \vec{B} + \frac{\vec{J}}{\sigma} \right)$$

or

$$\frac{\partial \vec{B}}{\partial t} = \nabla \times \left(\vec{v} \times \vec{B} \right) - \nabla \times \left(\eta \nabla \times \vec{B} \right) \quad \text{where } \eta \equiv \frac{1}{\mu \sigma}$$

To simplify further we can use $\nabla \times (\nabla \times \vec{a}) = \nabla (\nabla \cdot \vec{a}) - \nabla^2 \vec{a}$,

$$\frac{\partial \vec{B}}{\partial t} = \nabla \times \left(\vec{v} \times \vec{B} \right) - \eta \nabla^2 \vec{B}$$

We can introduce a new non-dimensional number called the magnetic Reynold's number, R_m

$$R_m = \frac{|\nabla \times \vec{v} \times \vec{B}|}{|\eta \nabla^2 \vec{B}|} \sim \frac{u_0 L}{\eta}$$

Typically velocity and length scales are much larger than η and this results in $R_m \gg 1$ and diffusivity can be neglected (this is considered idealized)⁸;

$$\frac{\partial \vec{B}}{\partial t} = \nabla \times \left(\vec{v} \times \vec{B} \right)$$

In this case, the magnetic field lines are similar to elastic bands frozen in the vector field.^{5,8} This means that any flux line through a closed loop will be conserved and the magnetic flux lines provide a restoring force to a disturbance. If, however, the gradient of the magnetic field is very large, diffusion can no longer be neglected.

Now we can revisit Figure 1 and discuss the evolution of this process further. In Figure 1a, normal magnetic flux lines exist in anti-parallel directions. In Figure 1b, a perturbation pushes outward (not shown) and the ideal magnetic flux lines respond with a restoring force. As the perturbation grows and the restoring force grows, the magnetic flux lines become closer and closer. This increases the gradient of the magnetic field and diffusion sets in. In Figure 1d, magnetic flux lines diffuse and reconnect. In the Sun this perturbation is a manifestation of differential rotation rates that tend to twist the magnetic field lines. In tokomaks, this perturbation is caused from a kink in the magnetic field due to poloidal and toroidal magnetic interactions.^{2,9,19,20,21} This will be discussed in the next section.

2 Sawtooth Instabilities in Tokamak Devices

Tokamak plasmas are generally susceptible to two types of instabilities, microscopic and macroscopic. Microscopic instabilities generally dictate transport properties of a confined plasma, but in general do not cause significant disruption of confinement. Macroscopic instabilities however, can and often do result in total loss of plasma confinement.⁹ Sawtooth instabilities are unique in that they are macroscopic instabilities but do not result in a termination of discharge.⁹ They can however trigger other instabilities. In this section, we will discuss the characteristics of sawtooth instabilities in tokamak devices to include; cycle characteristics, energy transport, and problems associated with sawtooth instabilities. We will then discuss the current theories on causes of sawtooth instabilities and the methods of controlling them.

2.1 Sawtooth Characteristics

Sawtooth characteristics were discovered in 1974 and have now been verified on all tokamak devices.⁹ Sawtooth instabilities are periodic redistributions of core plasma and exist in three phases(Figure 4);²

- an approximately linear increase in both plasma temperature and density
- an oscillatory precursor phase
- a final rapid drop in both temperature and plasma density.

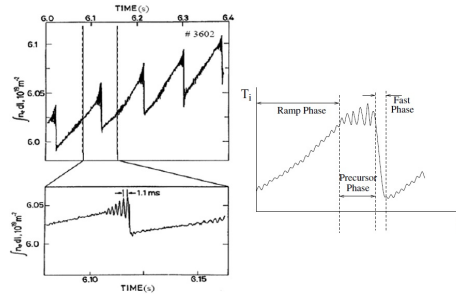

Figure 4: Sawtooth characteristic from JET showing all three phases²

When a sawtooth crash occurs, high energy electrons diffuse to cooler portions of the plasma resulting in a flattening T_e profile. This characteristic can be seen in both Figures 5 and 6.

2.2 Tokamak Plasma Stability

Before we can discuss the theories for sawtooth instabilities, we need to qualitatively discuss confined plasma stability. To do this we will discuss the safety factor, $q = \frac{m}{n}$ where m is the poloidal number and n is the toroidal number.

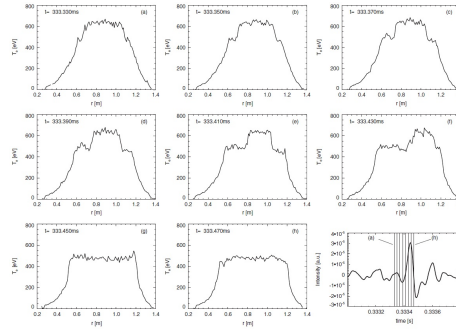

Figure 5: Electron temperature profile every $20\mu s$. In f, the temperature flattens out more on the interior where the higher magnetic field exists. The crash occurs between frames f and g.³

Figure 6: Two dimensional profile of electron temperature during sawtooth crash. Similar flattening characteristics on the interior side can be seen.¹⁹

Essentially the safety factor is the ratio to the number of times a field line will go around toroidally for one poloidal circuit.¹³ A more in depth review of MHD stability theory than is provided here will show that low rational numbers for q are least stable and tend to develop helical perturbations that can lead to kinks.¹³ An interesting result of MHD stability analysis is that if an $m = n = 1$ kink instability exists (Figure 7), the central safety factor, q_0 , must be greater than one to diminish the perturbation.¹² The large gradient of magnetic field can cause a transition from ideal to diffusion MHD where magnetic reconnection can occur.^{Priest} This is where Kadomtsev comes in.

2.3 Sawtooth Theories

The initial theory for the cause of sawtooth instabilities was by Boris Kadomtsev who postulated that the cycle begins with an $m = n = 1$ kink instability where the central safety factor $q_0 < 1$.^{2,9,19} Kadomtsev postulated that the kink

Figure 7: View of normal and $m = n = 1$ kink instability in a tokamak.⁹

instability would drive magnetic reconnection to restore a stable reconfiguration causing a transient the re-established a $q_0 > 1$ condition in the plasma. This is postulated to occur due to the kink mode creates a crowding of flux surfaces on one side triggering separation and the formation of a magnetic island. As the magnetic island grows, surfaces with equal helical flux will touch and reconnect (See Figure 8).² Ohmic heating was then thought to be responsible for driving T_e up and forcing $q_0 < 0$ to restart the cycle.⁹ Kadomtsev's model has been the standard driving much of the research in sawtooth oscillations.

Figure 8: (i) Magnetic flux surfaces prior to reconnection (ii) Reconnection of flux surfaces (iii) Deformation of magnetic island (iv) Complete reconnection.²

Initial experiments indeed supported the Kadomtsev model¹⁷, but as devices got larger and data collection became more accurate, discrepancies were noted.

One discrepancy is that expected central safety factors, q_0 , should be restored to a value greater than one after a sawtooth crash. However increased precision yield experimental measurements showing q_0 never reaches 1.0 post crash (See Figures 9 and 10). This is indicative that full Kadomtsev reconnection is not occurring and has led to a theory that Kadomtsev reconnection is interrupted due to rapid heat diffusion through the reconnection region.²⁰

Figure 9: q_0 for TEXTOR.⁹

Figure 10: q_0 measurements on the TFTR.¹⁹

Additional data has been collected that deviates from the Kadomtsev model. Reconnection times are significantly faster than those predicted by the Kadomtsev model, since the Kadomtsev model incorporates the Sweet-Parker model for reconnection. Reconnection theory predicts sawtooth crash times of $\tau_K \approx 340\mu s$

while actual sawtooth crashes occur on timescales $\leq 20\mu s$.^{2,3,19} As Chapman explains, this is not surprising since the Sweet-Parker model of reconnection is only applicable to collisional plasmas, while tokamak plasmas have a collisionless behavior.

These contradictions have led to many additional theories on the cause of sawtooth crashes and the current widely accepted theory is a modified Kadomtsev model with interrupted reconnection.² The partial reconnection model is initialized with a kink instability and begins reconnection per the Kadomtsev model. However, full reconnection is interrupted due to the faster heat diffusion than magnetic diffusion. This heat conduction minimizes the pressure gradient driving the kink mode.²⁰ This causes the magnetic island to reach a critical width and creates two regions undergoing different relaxation processes, the core and the magnetic island.¹⁵ This creates a complex diffusion event of two current sheets during a subsequent sawtooth ramp.² Even this theory isn't complete because it relies still on having a kink instability precursor. There is evidence of precursor-less sawteeth and could imply that the kink mode instability is a consequence of some other factor rather than the cause of the collapse.⁹

2.4 Controlling Sawtooth Oscillations

There are two main techniques for controlling sawtooth oscillations; stabilizing the oscillations to lengthen the time between crashes and destabilizing the oscillations to minimize the amplitude of crashes.² Stabilization of sawtooth oscillations will lengthen the period between sawtooth crashes and recent studies have shown that long period sawtooth oscillations can go on to cause other instabilities such as neo-classical tearing modes (NTMs) and edge localized modes (ELMs).² Additionally, fast helium alpha particles from fusion reactions is thought to actually stabilize sawtooth oscillations.^{4,6} Because of this, most efforts to control sawtooth oscillations in ITER and future fusion devices are aimed at destabilizing sawtooth oscillations. Techniques to destabilize sawtooth oscillations aim to shorten the period by creating conditions conducive to sawtooth crashes. This minimizes the amplitude and shortens the period to reduce the potential for causing NTMs and ELMs. An added benefit is that small amplitude sawtooth oscillations can aid in preventing an accumulation of helium ash in tokamak fusion devices.²

2.4.1 Counter Current Neutral Beam Injection (NBI)

In typical co-current NBI, neutral atoms are injected into the plasma in the same toroidal direction as the plasma current. In counter current NBI, neutral atoms are injected in the opposite direction of the toroidal plasma current¹⁰ It was found using the MAST device that by injecting neutral particles in the counter current direction, sawtooth oscillation periods were reduced (Figure 11).⁴

Figure 11: Sawtooth period vs. NBI. Here negative velocities are for counter current NBI while positive are co-current NBI.⁴

2.4.2 Cyclotron Current Drive

Another technique discussed in destabilizing sawtooth oscillations in ITER is the use of ion and electron cyclotron current drive (ECCD and ICCD).⁴ Cyclotron current drive is the result of selectively heating ions or electrons traveling in one toroidal direction. This selective heating will give those particular ions or electrons a greater contribution to the driving current.¹⁴ Driving current using either ECCD or ICCD is thought to raise the magnetic shear at the magnetic island core interface causing earlier sawtooth oscillation destabilization.⁴

2.4.3 Additional Considerations for ITER

A recent study on electron cyclotron resonance heating (ECRH) in the KSTAR device in South Korea resulted in the development of multiple flux tubes that stabilized sawtooth oscillations, delaying crashes. This new data suggests that ECRH has a side effect of lengthening sawtooth oscillations periods promoting detrimental NTMs and ELMs. This is of concern for ITER because ITER will use ECRH as major heating and current drive mechanism.^{1,21}
